

**1. Considerations for Data Users**

The annual NO<sub>2</sub> estimates from 1984 to 2012 have been derived from models based on annual measured NO<sub>2</sub> levels from National Air Pollution Surveillance monitoring stations for 24 Census Divisions. These annual estimates were calculate by applying factors derived from annual observed measures from the National Air Pollution Surveillance (NAPS) monitors to the results of a land use regression (LUR) model developed by Dr. Perry Hystad circa 2006 (the base year)<sup>1</sup>. In effect, these factors either raise (for years prior to 2006) or lower (for years after 2006) all NO<sub>2</sub> estimates from the LUR model by the same amount for a given year within each region.

The annual NO<sub>2</sub> estimates from 2013 to 2016 have been derived from provincial average of annual measured NO<sub>2</sub> levels from National Air Pollution Surveillance monitoring stations that were classified as general population exposure and regional background. These annual estimates were calculated by applying factors derived from annual observed NO<sub>2</sub> measures from the National Air Pollution Surveillance (NAPS) monitors to 2012 annual NO<sub>2</sub> estimates that was derived from modelled values for 24 Census Divisions (i.e. NO2LUR\_A\_12.csv).

The approach used to derive the 2012 annual NO<sub>2</sub> estimates (i.e. NO2LUR\_A\_12.csv) inherently allows for the potential that over time NO<sub>2</sub> levels changed at a different rate across Canada. Taking into consideration these geographic differences in temporal adjustments is important because they can impact the magnitude of exposure gradients between people in different areas depending upon year.

It was assumed that using the 2012 annual NO<sub>2</sub> estimates rather than the 2006 annual NO<sub>2</sub> estimates<sup>1</sup> as the base year would be a better representation of spatial gradients as the former estimates account for changes in emission sources between 2006 and 2012 by incorporated geographic differences in temporal adjustments

**2. Calculating annual factors**

For each Province, CANUE Staff used the below equation to calculate an annual predicted NO<sub>2</sub> level for 2013 to 2016 (shown in column A in Table 1), then the ratio of each year’s predicted level compared to the 2012 predicted level was calculated (shown in column C in Table 1). For each Province, annual factors were calculated for each year (2013 - 2016). Note that the ratio method for producing annual factors has been used previously in Canada<sup>2</sup> and Europe<sup>3</sup>.

$$\text{Annual Predicted NO}_2 = \frac{\text{Average NO}_2 \text{ level from NAPS stations in province, } P, \text{ for year, } Y}{\text{Average NO}_2 \text{ level from NAPS stations in province, } P, \text{ for year, } 2012} \times \text{2012 Annual Predicted NO}_2 \text{ level}$$

It should be noted that only National Air Pollution Surveillance monitoring stations that were classified as general population exposure and regional background were used in deriving the annual factors.

**3. Applying the annual factors**

Using the 2012 estimates that were based on the 2006 NO<sub>2</sub> model, estimates of annual average NO<sub>2</sub> (ppb) were made for every single-link DMTI Spatial Inc postal code location in use in 2012 by Dr. Perry Hystad, Oregon State University. CANUE staff assigned each postal code a province ID, and applied the appropriate province-specific annual factors, resulting in 4 annual files (2013-2016) containing NO<sub>2</sub> estimates.

Table 1. Calculation example for Province ID, 35 (Ontario), for 2012-2016

Year	A Annual predicted NO <sub>2</sub> level	B 2012 predicted NO <sub>2</sub> level	C Annual factor Ratio A/B
2016	16.3	18.6	0.88
2015	17.4	18.6	0.93
2014	17.7	18.6	0.95
2013	17.3	18.6	0.93
2012	18.6	18.6	1
